Abstract

Typical techniques for sequence classification are designed for well-segmented sequences which has been edited to remove noisy or irrelevant parts. Therefore, such methods cannot be easily applied on noisy sequences which are expected in real-world applications. We present the Temporal Attention-Gated Model (TAGM) which is able to deal with noisy sequences. Our model assimilates ideas from attention models and gated recurrent networks. Specifically, we employ an attention model to measure the relevance of each time step of a sequence to the final decision. We then use the relevant segments based on their attention scores in a novel gated recurrent network to learn the hidden representation for the classification. More importantly, our attention weights provide a physically meaningful interpretation for the salience of each time step in the sequence. We demonstrate the merits of our model in both interpretability and classification performance on a variety of tasks, including speech recognition, textual sentiment analysis and event recognition.

1. Introduction

Sequence classification is posed as a problem of assigning a single label to a sequence of observations. Sequence classification models have extensive applications ranging from computer vision to natural language processing. Most existing sequence classification models (e.g., hidden-state conditional random field (HCRF) [29] and hidden-unit logistic model (HULM) [25]) follow the basic framework that focuses on learning an effective hidden representation in a supervised way to capture both the latent structure in feature space and temporal information along the time domain. These types of methods are designed for well segmented sequences without irrelevant (noisy) parts that could

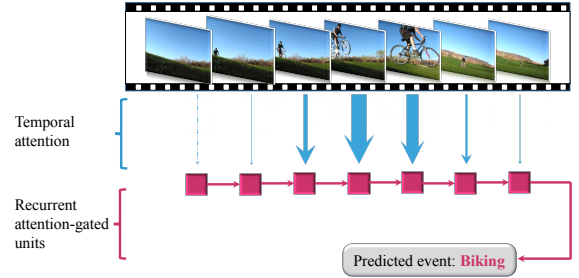

Figure 1. The model proposed in this work first employs an attention module to extract the salient frames from the raw noisy input sequences, and then learns an effective hidden representation for the top classifier. The wider the flow line is, the more the information is incorporated into the hidden representation. The dash line represents the zero input.

mislead the classifier. As a result, these models require the input sequences to be pre-processed to remove the irrelevant subsequences, thereby avoiding the interference of irrelevant information. However, the pre-processing step is normally performed in a handcrafted way and hence quite inconvenient and expensive for various real-world tasks which do not provide pre-segmented data. The problem can be circumvented by gated recurrent networks like Gated Recurrent Units [4] and Long Short-Term Memory [11]. They employ gates to balance the information flow from the current and previous time steps. Nevertheless, these methods model the gates w.r.t. each hidden unit instead of whole time step, thus it is hard to interpret the importance of each time step for the final decision. Another way to detect salient segments, as we do in this work, is the adoption of attention-based mechanism, which models how much attention should be paid to a specific segment. In this work, we combine the ideas from attention models and gated recurrent networks to propose an attention-based sequence classification model which is able to automatically localize the salient segments which are relevant to the final decision and ignore the irrelevant (noisy) parts of a raw sequence. Consequently, the decision made based on the selected rel-

†tbaltrus@cs.cmu.edu

‡D.M.J.Tax@tudelft.nl

§morency@cs.cmu.edu

evant segments is more accurate than the conventional models that take into account the whole sequence. We refer to the resulting model as Temporal Attention-Gated Model (TAGM). Figure 1 presents a high-level overview for it.

Notably, compared to conventional sequence classification models, TAGM benefits from the following advantages:

- It is able to automatically capture salient parts of the input sequences thereby leading to better performance.
- The inferred salience (scalar) scores provide a physically meaningful interpretation with respect to the informativeness of the raw input sequence along the time domain.
- Compared to conventional gated recurrent models such as LSTM, our model reduces the number of parameters which leads to faster training and inference and better generalizability with less training data.
- The proposed model is able to generalize to tasks in computer vision, speech recognition, and natural language processing.

2. Related Work

This work is related to three main areas including sequence classification, attention models and recurrent networks. Covering fully each of them would be beyond the scope of this paper due to the limited space.

Sequence Classification. The conventional sequence classification models can be divided roughly into two categories.

The first category focuses on learning an effective intermediate representation based on generative models. These methods are typically based on the use of (kernels based on) the hidden Markov models (HMMs) [30] or dynamic time warping (DTW) [15]. The HMM is a generative model which models the sequence data in a chain of latent k-nomial features. It can be extended to class-conditional HMMs for sequence classification by combining class priors via Bayes' rules. HMM can also be used as the base model for Fisher Kernel [14] to learn a sequence representation.

The second category is the discriminative graphical models which model the distribution over all class labels conditioned on the input data. Conditional random fields (CRF) [21] are discriminative models for sequence labeling. A potential drawback of common linear-chain CRFs is that the linear nature cannot model complex decision boundaries. To address this limitation, many models (e.g., latent-dynamic CRFs [28], conditional neural fields [26], neural conditional random fields [5] and hidden-unit CRF model [37]) are proposed to model the latent nonlinear structure hidden in the data. Hidden-state CRF (HCRF) [29] employs a chain of k-nomial latent variables to model the latent structure and has been successfully used in the se-

quence classification. Similarly, hidden unit logistic model (HULM) [25] utilizes binary stochastic hidden units to represent the exponential hidden states so as to model more complex latent decision boundaries.

Aforementioned works are specifically designed for well segmented sequences and hence cannot cope well with noisy sequences. Our TAGM approach addresses this limitation through filtering out the noise.

Attention Models. Inspired by the attention scheme of human foveal vision, attention model was proposed to focus selectively on certain relevant parts of the input by measuring the sensitivity of output to variances of the input. Doing so can not only improve the performance of the model but can also result in better interpretability. Attention models have been applied to image and video captioning [39, 3, 6, 40], machine translation [1, 23, 31], depth-based person identification [10] and speech recognition [8]. Our model employs an attention model to measure the relevance of each time step and then serves as the gate value for the recurrent hidden representation learning.

Recurrent Networks. Recurrent Neural Networks (RNN) learn a representation for each time step by taking into account both the observation at current time step and the representation in the previous one [32]. The biggest advantage of recurrent neural networks lies in the capability of preserving information over time by the recurrent mechanism. Recurrent networks have been successfully applied to various tasks including language modeling [24], image generation [36] and online handwriting generation [7]. To address the gradient vanishing problem of plain-RNN when dealing with long sequence, LSTM [11] and GRU [4] were proposed. They are equipped with the gates to balance the information flow from the previous time step and current time step dynamically. Inspired by this setup, our model also employs a gate to filter out the noisy time steps and preserve the salient ones. But the difference from the LSTM and GRU is that the gate value in our model is fed from the attention module which focuses on the learning the salience of each time step.

3. Temporal Attention-Gated Model

The proposed model (TAGM) consists of two modules: Temporal Attention Module and Recurrent Attention-Gated Units. Suppose we are given a noisy sequence (e.g., a video) in which only some frames are useful for the final task (e.g., event recognition). Conditioned on this input sequence, TAGM is able to (1) calculate the salience of each time step over the input sequence, (2) construct a hidden representation based on the salience score and perform the final supervision task. The model can be trained in an end-to-end manner efficiently. The graphical structure of the model is illustrated in Figure 2.

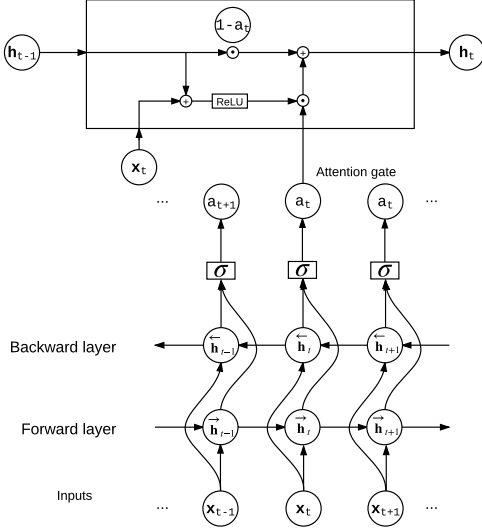

Figure 2. The graphical representation of the Temporal Attention-Gated Model. Note that a_t is a scalar value instead of a vector, hence \odot in the figure means multiplication between a scalar and a vector.

3.1. Recurrent Attention-Gated Units

We propose a module named Recurrent Attention-Gated Units to learn the hidden representation for the input sequence. In order to extract the relevant salience sections and ignore the irrelevant parts, we define an attention gate inserted into the recurrent unit in each time step to control how much information is incorporated from the input of the current time step based on the relevance to the final supervised task.

Specifically, given a raw sequence $\mathbf{x}_{1,\dots,T} = \{\mathbf{x}_1, \dots, \mathbf{x}_T\}$ of length T in which $\mathbf{x}_t \in \mathbb{R}^D$ denotes the observation at the t -th time step, the attention gate at time step t is denoted as a_t , which is a scalar value that indicates the relevance of current time step to the final decision. The hidden state at time step t is modeled as:

$$\mathbf{h}_t = (1 - a_t) \cdot \mathbf{h}_{t-1} + a_t \cdot \mathbf{h}'_t \quad (1)$$

Wherein, \mathbf{h}'_t is the candidate state value which fully incorporates the input information \mathbf{x}_t in the current time step:

$$\mathbf{h}'_t = g(\mathbf{W} \cdot \mathbf{h}_{t-1} + \mathbf{U} \cdot \mathbf{x}_t + \mathbf{b}) \quad (2)$$

Herein, \mathbf{W} , \mathbf{U} are respectively the linear transformation parameters for previous and current time steps while \mathbf{b} is the bias term. We use the rectified linear unit (ReLU) as the activation function g . Equation 1 would make a balance between current candidate hidden state and previous (candidate) hidden state with attention gate a_t . High attention value would push the model to focus more on the current hidden state and input feature, while low attention value

would make the model ignore the current input feature and inherit more information from previous time steps.

The learned hidden representation in the last time step \mathbf{h}_T is further fed into the top classifier such as softmax to perform classification task, which calculates the probability of a predicted label y_k among K classes as:

$$P(y_k | \mathbf{h}_T) = \frac{\exp\{\mathbf{W}_k^\top \mathbf{h}_T + b_k\}}{\sum_{i=1}^K \exp\{\mathbf{W}_i^\top \mathbf{h}_T + b_i\}} \quad (3)$$

3.2. Temporal Attention Module

We propose an attention-weighting mechanism to calculate the attention gate in Equation 1. To obtain a comprehensive summarization for each time step of the input sequence and thereby achieve an accurate attention value for the degree of salience, we take advantage of a bi-directional RNN. Specifically, the attention weight a_t at time step t is calculated by

$$a_t = \sigma(\mathbf{m}^\top (\vec{h}_t; \overleftarrow{h}_t) + b) \quad (4)$$

Herein, \mathbf{m} is linear transformation vector parameter and b is the bias term, \vec{h}_t and \overleftarrow{h}_t are the hidden representations of a bi-directional RNN model:

$$\vec{h}_t = g(\vec{\mathbf{W}} \mathbf{x}_t + \vec{\mathbf{U}} \vec{h}_{t-1} + \vec{\mathbf{b}}) \quad (5)$$

$$\overleftarrow{h}_t = g(\overleftarrow{\mathbf{W}} \mathbf{x}_t + \overleftarrow{\mathbf{U}} \overleftarrow{h}_{t+1} + \overleftarrow{\mathbf{b}}) \quad (6)$$

The ReLU is used as the activation function g . The utilization of bi-directional RNN makes the temporal attention module focus on current time steps and take into account the adjacent temporal information in both directions. Because we are modeling salience at each time step instead of summarizing the whole sequence, a plain RNN model is sufficient.

A sigmoid function is employed as the activation function σ after the linear transformation of hidden representation $(\vec{h}_t, \overleftarrow{h}_t)$ in Equation 4 to restrict the attention weight to lie between $[0, 1]$. The learned attention weights serve as the attention gate for the top hidden representation module (Recurrent Attention Gated Units) to control the involved information flow. Furthermore, another important role the learned attention weights play is to provide an interpretability about the degree of salience of each time step, which can be potentially used for applications such as sequence salience detection or sequence noise filtering.

3.3. Parameter Learning

Suppose we are given a training set $\mathcal{D} = \{(\mathbf{x}_{1,\dots,T}^{(n)}, y^{(n)})\}_{n=1,\dots,N}$ containing N sequences of length T (here $\mathbf{x}_t^{(n)} \in \mathbb{R}^D$ denotes the observation at the t -th time step of the n -th sample and T can differ from sample to sample) and their associated labels y . We learn all the parameters of three modules (i.e., attention

module, recurrent attention-gated units and top classifier (eg., softmax) of the TAGM by minimizing the conditional negative log-likelihood of the training data with respect to the parameters:

$$\mathcal{L} = - \sum_{n=1}^N \log P \left(\mathbf{y}^{(n)} | \mathbf{x}_{1,...,T}^{(n)} \right) \quad (7)$$

The model can be readily trained in an end-to-end manner. The loss is back-propagated through top hidden representation module and attention module successively using back-propagation through time algorithm [38]. We employ RM-Sprop as the gradient descent optimization algorithm with gradient clipping between -5 and 5 [2].

3.4. Comparison with LSTM and GRU

While our model is similar to RNN variants like GRU and LSTM, it is specifically designed with salience detection in mind and has four key differences when compare to them:

- We employ a bi-directional RNN instead of single direction RNN to take into account both the preceding and the following information of the sequence in the temporal attention module. It helps to model the temporal smoothness of attention distribution (demonstrated in Figure 4). It should be noted that it is different from the design of the gates in the bi-directional LSTM model since the latter just concatenates the hidden representations of two directional LSTM, which does not remedy the downside that each gate of them is still calculated by considering only one-directional information.
- We only focus on one scalar attention score to measure the relevance of the current time step instead of generally modeling gate value for each hidden unit as done by GRU and LSTM. In this way, we can obtain an interpretable salience detection (demonstrated in three tasks in Section 4).
- We separate the attention modeling and recurrent hidden representation learning as two independent modules to decrease the degree of coupling. One of the advantages would be we can customize the specific recurrent structure for each module with different complexity according to the requirements (eg., different size of hidden units in two modules of TAGM in Table 1).
- Our model only contains one scalar gate, namely the attention gate, rather than 2 vectorial gates in GRU and 3 gates in LSTM. Doing so enforces the attention gate to take full responsibility of modeling all the salience information and thereby maximize the discrimination. In addition, the model contains fewer parameters (compared to LSTM) and simpler gate structure with less redundancy (compared to GRU and LSTM) to train. It eases the training procedure and can

alleviate the potential over-fitting and have better generalization given small amount of training data, which is demonstrated in section 4.1.3.

4. Experiments

We performed experiments with TAGM on three different tasks with publicly available datasets of different modalities: (1) speech recognition on an audio dataset, (2) sentiment analysis on a text dataset, and (3) event recognition on a video dataset.

Experimental Setup shared across experiments. We validate the learning rate for parameters \mathbf{m} and b in Equation 4 to make the effective region of the sigmoid function of TAGM model adaptive to the specific data. Larger learning rate leads to sharper distribution of attention weights, namely, augment on more important time steps and overlook smaller weights.

For all the recurrent networks mentioned in this work (TAGM, GRU, LSTM and plain-RNN), the number of hidden units is tuned by selecting the best configuration from the option set $\{64, 128, 256\}$ using validation set. The dropout value is validated from the option set $\{0.0, 0.25, 0.5\}$ to avoid the potential overfitting.

4.1. Experiments with Synthetic Dataset

4.1.1 Dataset

We conduct preliminary experiments on a synthetic dataset constructed from the Arabic spoken digit dataset [9]. The Arabic spoken digit dataset contains 8800 utterances, which were collected by asking 88 Arabic native speakers to utter all 10 digits ten times. Each sequence consists of 13-dimensional MFCCs which were sampled at 11,025Hz, 16-bits using a Hamming window. We append the white noise to the beginning and the end of each sample to make them noisy. The length of the noise appended is randomized to ensure that the model does not learn to just focus on the middle of the sequence.

4.1.2 Experimental setup

We use the same data division as Hammami and Bedda [9]: 6600 samples as training set and left 2200 samples as test set. We further set aside 1100 samples from training set as the validation set. There is no subject overlap between the three sets.

We compare the performance of our TAGM with three types of baseline models:

Attention module + NN. One straightforward way to perform the subsequent classification after attention calculation is to employ a feed-forward neural network on the weighted sum of the different time steps:

$$\mathbf{v} = \sum_{t=1}^T a_t \cdot \mathbf{x}_t, \quad \mathbf{h} = g(\mathbf{W} \cdot \mathbf{v} + \mathbf{b}) \quad (8)$$

The obtained hidden representation \mathbf{h} is further fed into the softmax classifier as TAGM.

State-of-the-art sequence classification models. HCRF and HULM are both extensions of the conditional random fields (CRF [21]) by inserting hidden layers to model the non-linear latent structure in the data. The difference lies in the structure of hidden layers: HCRF uses a chain of k -nomial latent variables while HULM utilizes k binary stochastic hidden units.

Recurrent neural networks. Since our model is a recurrent network equipped with a gate mechanism, we compare it with other recurrent networks: plain-RNN, GRU, LSTM.

In the experiments of comparing the generalizability with the varying size of training data, we augment the size of training data from 1100 to 5500 increasingly to compare the performance of the three models. We select the best model configuration for hidden layers from the option set $\{64, 128, 256\}$ with the validation set.

4.1.3 Results

Comparison of generalizability with the varying size of training data. We first conduct experiments to compare the generalizability of TAGM to GRU and LSTM by varying the size of training data on the noisy Arabic dataset. Figure 3 presents the experimental results. It shows that TAGM exhibits better generalizability than GRU and LSTM when for training sizes of 1100 and 2200, which is probably caused by the fewer parameters to learn, avoiding overfitting for smaller training sizes.

Figure 3. The classification accuracy on the noisy Arabic speech dataset as a function of the size of training data.

Sequence Saliency Detection. In order to evaluate the performance of sequence saliency detection by our Temporal Attention-Gated model, we visualize the attention weights of our model trained on the noisy Arabic dataset, which is illustrated in Figure 4. It shows that the attention model can correctly detect the informative saliency part from the raw dataset.

To investigate the effect of the temporal information contained in the hidden representation, we also visualize the

Figure 4. The visualization of attention weights of TAGM on 10 samples (one sample in each category). For each subfigure, the top subplot shows the spectrogram of the original sequence data, the bottom subplot shows the attention values a_t over time. The red lines indicate the groundtruth of salient segments.

Figure 5. The visualization of attention weights of Attention module+NN: the weighted features are fed into Feed-forward Neural Networks .

attention weight of the Attention module + Neural Network classifier, which is shown in Figure 5. It shows that the TAGM results in a cleaner and more smooth attention weight profile, notice the spiky behavior, which is mainly achieved by the temporal modeling in recurrent way.

Evaluation of Classification Performance Table 1 presents the classification performance of several sequence classifiers on Arabic dataset. In order to investigate the effect of the manually added noise information, we perform experiments on both clean and noisy versions of data.

While the Plain-RNN completely fails because of the interference by the noise, other three recurrent models with gate-setup do not suffer from the noise and obtain comparable (even better by GRU and TAGM) performance with the state-of-the-art result achieved by HCRF on clean data. Our model achieves the best result among all classifiers with single-directional recurrent configuration. GRU also obtains very good performance which is better than LSTM, this probably results from better generalization of our model and GRU compared to LSTM on the relatively small dataset due to the simpler gate setup. We also perform experiments with the bidirectional version of GRU, LSTM and TAGM, in which our Bi-TAGM performs best. Bi-GRU achieves its best performance with 64 hidden units. It is worth mentioning that our (single-directional) TAGM using 47 K parameters already achieves comparable result with the Bi-LSTM and Bi-GRU, which indicates that the bi-directional mechanism in the attention module of TAGM enables it to capture most bi-directional information.

4.2. Sentiment Analysis

Sentiment analysis in language is a popular research topic in the field of natural language processing (NLP)

Table 1. Classification accuracy (%) on Arabic spoken dataset by different sequence classification models. Asterisked models (*) perform on the clean version of data. Herein, “AM-NN” denotes the Attention Module + Neural Network classifier. The best model configuration for hidden layers is selected from option set {64, 128, 256} for each model. Note that we can customize different size of hidden units for two modules of TAGM, eg., 128-64 means 128 hidden units for temporal attention module and 64 hidden units for recurrent attention-gated units. See text for details.

Model	H	Parameters	Accuracy
HULM* [25]	—	—	95.32
HCRF* [25]	—	—	96.32
HULM	—	—	88.27
HCRF	—	—	90.41

Bi-TAGM	128-128	83 K	97.91

which requires to consider not only the key words with strong sentiment but also the semantic compositionality between phrases. Hence our model is a good fit for this task, herein one sentence can be considered as a sequence of which each word corresponds to a time step.

4.2.1 Dataset

The Stanford Sentiment Treebank (SST) [34] is a data corpus of movie review excerpts. It consists of 11855 sentences each of which is assigned a score to indicate the sentimental attitude towards the movie reviews. 215,154 phrases are obtained from parsing all sentences by the Stanford Parser [19]. Both the sentence-level and phrase-level labels are provided with two resolutions: binary-classification task and fine-grained (5-class) task.

4.2.2 Experimental Setup

We utilize 300-d *Glove* word vectors pretrained over the Common Crawl [27] as the features for each word of the sentences. Our model is well suitable to perform sentiment analysis using sentence-level labels. Nevertheless, we also perform experiments with both the labels in two levels so as to have a fair and intuitive comparison with state-of-the-art baselines.

Following Socher et al. [34], we apply the fixed data division: 8544/1101/2210 samples are used for training, validation and test respectively while the corresponding splits are 6920/872/1821 in the binary classification task.

4.2.3 Results

Sequence Salience Detection In order to investigate the performance of salience detection by our model on SST

Table 2. Classification accuracy (%) on Stanford Sentiment Tree-Bank dataset by different models. We conduct experiments on both binary and fine-grained (5-class) classification tasks. Herein, all models are trained with **only sentence-level labels**. See text for details.

data, we visualize the calculated attention weights for each word in the test sentences. Group (a) in Figure 6 presents a number of examples that are predicted correctly by our model in the binary-classification task. It shows that our model is able to successfully capture the key sentimental words and omit irrelevant words, even for the sentences with complicated syntax. We especially test the examples that include negated expressions.. As shown in the last two sentences in (a), our model can deal with them very well. We also investigate the samples our model fails to predict. As shown in (b) of Figure 6, it seems that the strongly sentimental words would mislead our model in the sentences with very confusing context. In this case, it is very hard for the model to understand the intention hidden behind the words.

Evaluation of Classification Performance We conduct two sets of experiments to evaluate the performance of our model with the comparison to the baseline models. Since our model is designed for general noisy sequence modeling instead of syntax-oriented sentence modeling, it is more suitable to only use sentence-level labels, although phrase-level labels are also provided in SST dataset. Table 2 shows the experimental results of several sequential

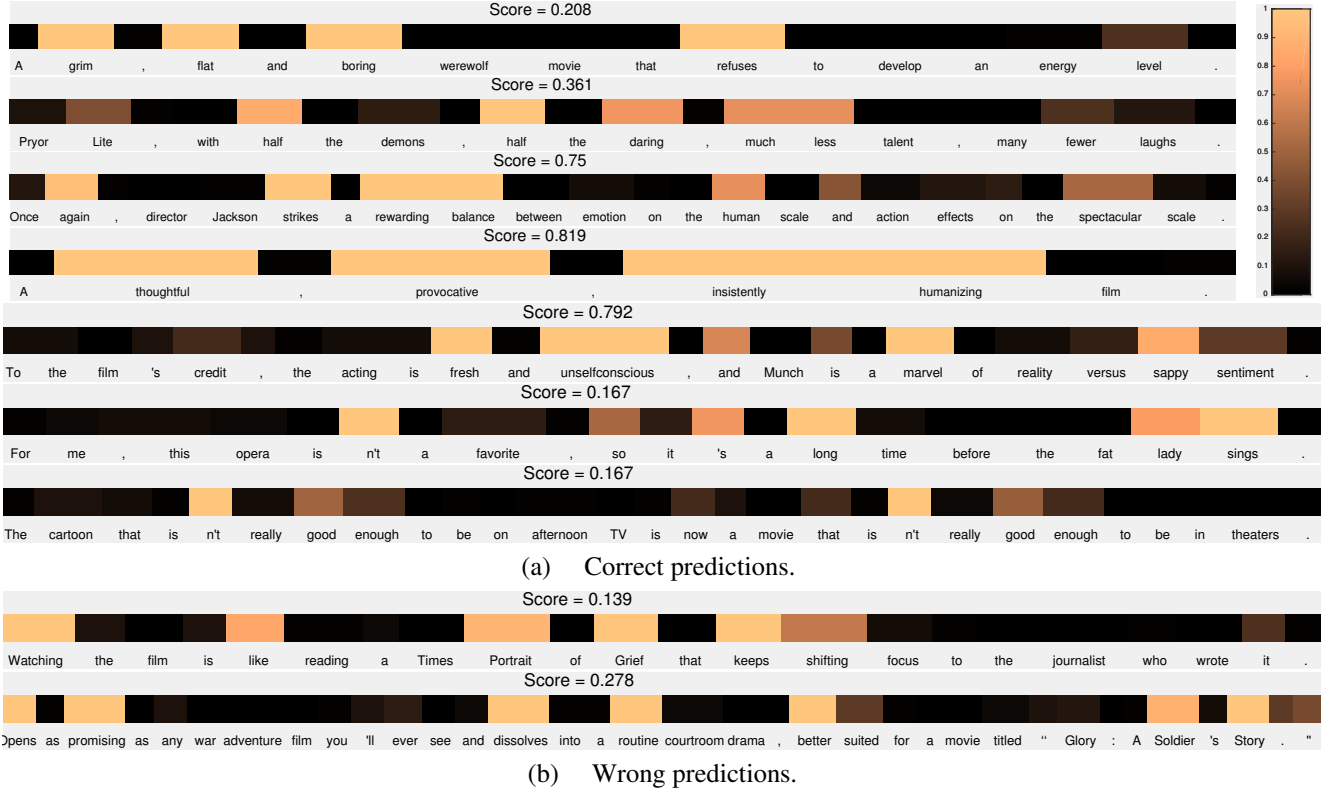

Figure 6. The visualization of attention weights of Recurrent Attention Model: (a) correct predictions and (b) wrong predictions. The scores displayed are the groundtruth label indicating the writer’s overall intention for this review.

models with only sentence-level labels. Our model achieves the best result in both binary classification task and fine-grained (5-class) task. LSTM and GRU outperform plain-RNN model due to the information-filtering capability performed by additional gates. It is worth mentioning that our model achieves better performance than LSTM with only half the hidden parameters.

To have a fair comparison with the existing sentimental analysis models, we conduct the second set of experiments with both sentence-level and phrase-level labels. The results are presented in Table 3. It shows that our model outperforms most of the existing models and achieves comparable accuracy with the state-of-the-art results. It actually obtains overall best results considering both binary and fine-grained cases. This is an encouraging result, in particular, since our model is not specifically designed towards NLP tasks.

4.3. Event recognition

4.3.1 Dataset

Columbia Consumer Video (CCV) Database [17] is an unconstrained video database collected from YouTube without any post-editing. It consists of 9317 web videos with the average duration of 80 seconds (210 hours in total). Except some negative background videos, each video is manually

annotated into one or more of 20 semantic categories such as ‘basketball’, ‘ice skating’, ‘biking’, ‘birthday’ and so on. It is a very challenging database due to the many noisy and irrelevant segments contained inside.

4.3.2 Experimental setup

Following Jiang et al [17], we use the fixed training/test division: 4659 videos as the training set and 4658 as the test set. We compare our model with the baseline method [16] on this dataset, which performs classification with SVM on the Bag-of-words representations of each of several popular features separately and then combines the results using late fusion. Its experimental results show that CNN features performs best among all features they tried, hence we choose to use CNN features with the same setup, i.e., the outputs (4,096 dimensions) of the seventh fully-connected layer of a pre-trained AlexNet model [20]. For the sake of computational efficiency, we extract CNN features with sampling rate 1/8 (one frame every eight).

Since more than one event (correct label) can happen in a sample and mean average precision (mAP) is typically used as the evaluation metric for CCV [17, 16], we perform binary classification for each category but train them jointly, hence the prediction score for each category is calculated by

Figure 7. The calculated attention weights of Temporal Attention-Gated Model for examples from test set of CCV database. The attention weight is indicated for selected representative frames. Our TAGM is able to capture the action of ‘riding bike’ for the event ‘biking’, ‘cake’ for the event ‘birthday’ and ‘infield zone’ for ‘baseball’. A video containing these three complete sample sequences is presented in the supplemental material.

a sigmoid function instead of softmax equation 3:

$$P(y_k = 1|\mathbf{h}_T) = \frac{1}{1 + \exp\{-(\mathbf{W}_k^T \mathbf{h}_T + b_k)\}} \quad (9)$$

and joint binary cross-entropy over K categories is minimized:

$$\mathcal{L} = - \sum_{n=1}^N \sum_{k=1}^K \left[\log P(y_k = 1|\mathbf{h}_T) + \log(1 - P(y_k = 0|\mathbf{h}_T)) \right]$$

4.3.3 Results

Sequence Saliency Detection. Saliency detection for CCV database is an extremely difficult but appealing task due to complex and long scenes in videos. We select some representative frames from a video and check the corresponding learned attention weights to gain the insight about the performance of saliency detection of our model. Figure 7 shows some examples where TAGM correctly locates the salient subsequences by the attention weights. Our model is able to capture the relevant action, object or scene to the event, e.g., the action of riding bike for the event ‘biking’, cake for the event ‘birthday’ and baseball playground for the event ‘baseball’. It is interesting to note that the frame with the score 0.42 in event ‘baseball’ achieves the high score probably because of the real-time screen in the top right corner.

Evaluation of Classification Performance. We compare our model with the event recognition system [16]. Table 4 presents the performance of both models. Although it is not a fair comparison due to the fact that the baseline method employs the one-vs-all strategy to train a separate classifier for each event whereas our model train all events jointly in a single classifier. Our model still achieves an encouraging result since it is quite a challenging task for TAGM to

Table 4. Mean Average Precision (mAP) of baseline and our model on CCV dataset. See text for details.

Model	Training strategy	Feature	mAP
BOW+SVM +late average fusion	Separately (one-vs-all)	SIFT	0.52
		STIP	0.45
		SIFT+STIP	0.55
		CNN	0.67
TAGM	Jointly	CNN	0.63

capture salient sections for 20 events with complex scenes simultaneously. Moreover, our TAGM can provide a meaningful interpretability which is the prime superiority over the baseline model (BOW+SVM).

5. Conclusion

In this work, we presented the Temporal Attention-Gated Model (TAGM), a new model for noisy sequence classification. The model combines the ideas from attention model and gated recurrent networks to detect salient segments and filter out the noisy ones. The resulting hidden representation suffers less from the effect of noise and thereby improving the final classification performance. Furthermore, the learned attention scores provide a physically meaningful interpretation of relevance of each time step (subsequence) to the final decision. This has many potential applications such as sequence noise reduction, sequence key-frame detection, understanding what the classifier makes the final decision based on. The results of experiments with TAGM on several tasks show that our model performs well and is able to effectively locate the key frames (subsequences) of a sequence which is crucial to the final decision on three diverse challenging applications.

This study is an initial investigation into modeling noisy sequences combining attention model and recurrent net-

works. We foresee several extensions of this work in two aspects including the model and the application. We aim to incorporate reinforcement learning in the learning of attention module. Specifically, the feedback of classification performance in current iteration of parameter update would affect the update of attention module in the next iteration in an explicit way, thus there could be a reward or feedback loop from the hidden representation back to the attention module. Our model can also be potentially applied to abstract summarization in the NLP research, whose output is the sequential prediction instead of classification. In addition, document classification is also a suitable application for our model.
